Summary of the Amazon DynamoDB Service Disruption in the Northern Virginia (US-EAST-1) Region

We wanted to provide you with some additional information about the service disruption that occurred in the N. Virginia (us-east-1) Region on October 19 and 20, 2025. While the event started at 11:48 PM PDT on October 19 and ended at 2:20 PM PDT on October 20, there were three distinct periods of impact to customer applications. First, between 11:48 PM on October 19 and 2:40 AM on October 20, Amazon DynamoDB experienced increased API error rates in the N. Virginia (us-east-1) Region. Second, between 5:30 AM and 2:09 PM on October 20, Network Load Balancer (NLB) experienced increased connection errors for some load balancers in the N. Virginia (us-east-1) Region. This was caused by health check failures in the NLB fleet, which resulted in increased connection errors on some NLBs. Third, between 2:25 AM and 10:36 AM on October 20, new EC2 instance launches failed and, while instance launches began to succeed from 10:37 AM, some newly launched instances experienced connectivity issues which were resolved by 1:50 PM.

DynamoDB

Between 11:48 PM PDT on October 19 and 2:40 AM PDT on October 20, customers experienced increased Amazon DynamoDB API error
N. Virginia (us-east-1) Region. During this period, customers and other AWS services with dependencies on DynamoDB were unable to e
connections to the service. The incident was triggered by a latent defect within the service's automated DNS management system that
endpoint resolution failures for DynamoDB.

SDN LABS

Many of the largest AWS services rely extensively on DNS to provide seamless scale, fault isolation and recovery, low latency, and locality. Services like DynamoDB maintain hundreds of thousands of DNS records to operate a very large heterogeneous fleet of load balancers in each Region. Automation is crucial to ensuring that these DNS records are updated frequently to add additional capacity as it becomes available, to correctly handle hardware failures, and to efficiently distribute traffic to optimize customers' experience. This automation has been designed for resilience, allowing the service to recover from a wide variety of operational issues. In addition to providing a public regional endpoint, this automation maintains additional DNS endpoints for several dynamic DynamoDB variants including a FIPS compliant endpoint, an IPv6 endpoint, and account-specific endpoints. The root cause of this issue was a latent race condition in the DynamoDB DNS management system that resulted in an incorrect empty DNS record for the service's regional endpoint (**dynamodb.us-east-1.amazonaws.com**) that the automation failed to repair. To explain this event, we need to share some details about the DynamoDB DNS management architecture. The system is split across two independent components for availability reasons. The first component, the DNS Planner, monitors the health and capacity of the load balancers and periodically creates a new DNS plan for each of the service's endpoints consisting of a set of load balancers and weights. We produce a single regional DNS plan, as this greatly simplifies capacity management and failure mitigation when capacity is shared across multiple endpoints, as is the case with the recently launched IPv6 endpoint and the public regional endpoint. A second component, the DNS Enactor, which is designed to have minimal dependencies to allow for system recovery in any scenario, enacts DNS plans by applying the required changes in the Amazon Route53 service. For resiliency, the DNS Enactor operates redundantly and fully independently in three different Availability Zones (AZs). Each of these independent instances of the DNS Enactor looks for new plans and attempts to update Route53 by replacing the current plan with a new plan using a Route53 transaction, assuring that each endpoint is updated with a consistent plan even when multiple DNS Enactors attempt to update it concurrently. The race condition involves an unlikely interaction between two of the DNS Enactors. Under normal operations, a DNS Enactor picks up the latest plan and begins wor
the service endpoints to apply this plan. This process typically completes rapidly and does an effective job of keeping DNS state freshly
Before it begins to apply a new plan, the DNS Enactor makes a one-time check that its plan is newer than the previously applied plan. A
Enactor makes its way through the list of endpoints, it is possible to encounter delays as it attempts a transaction and is blocked by another DNS
Enactor updating the same endpoint. In these cases, the DNS Enactor will retry each endpoint until the plan is successfully applied to all endpoints

Polynomial-Time Algorithms for Prime Factorization and Discrete Logarithms on a Quantum Computer*

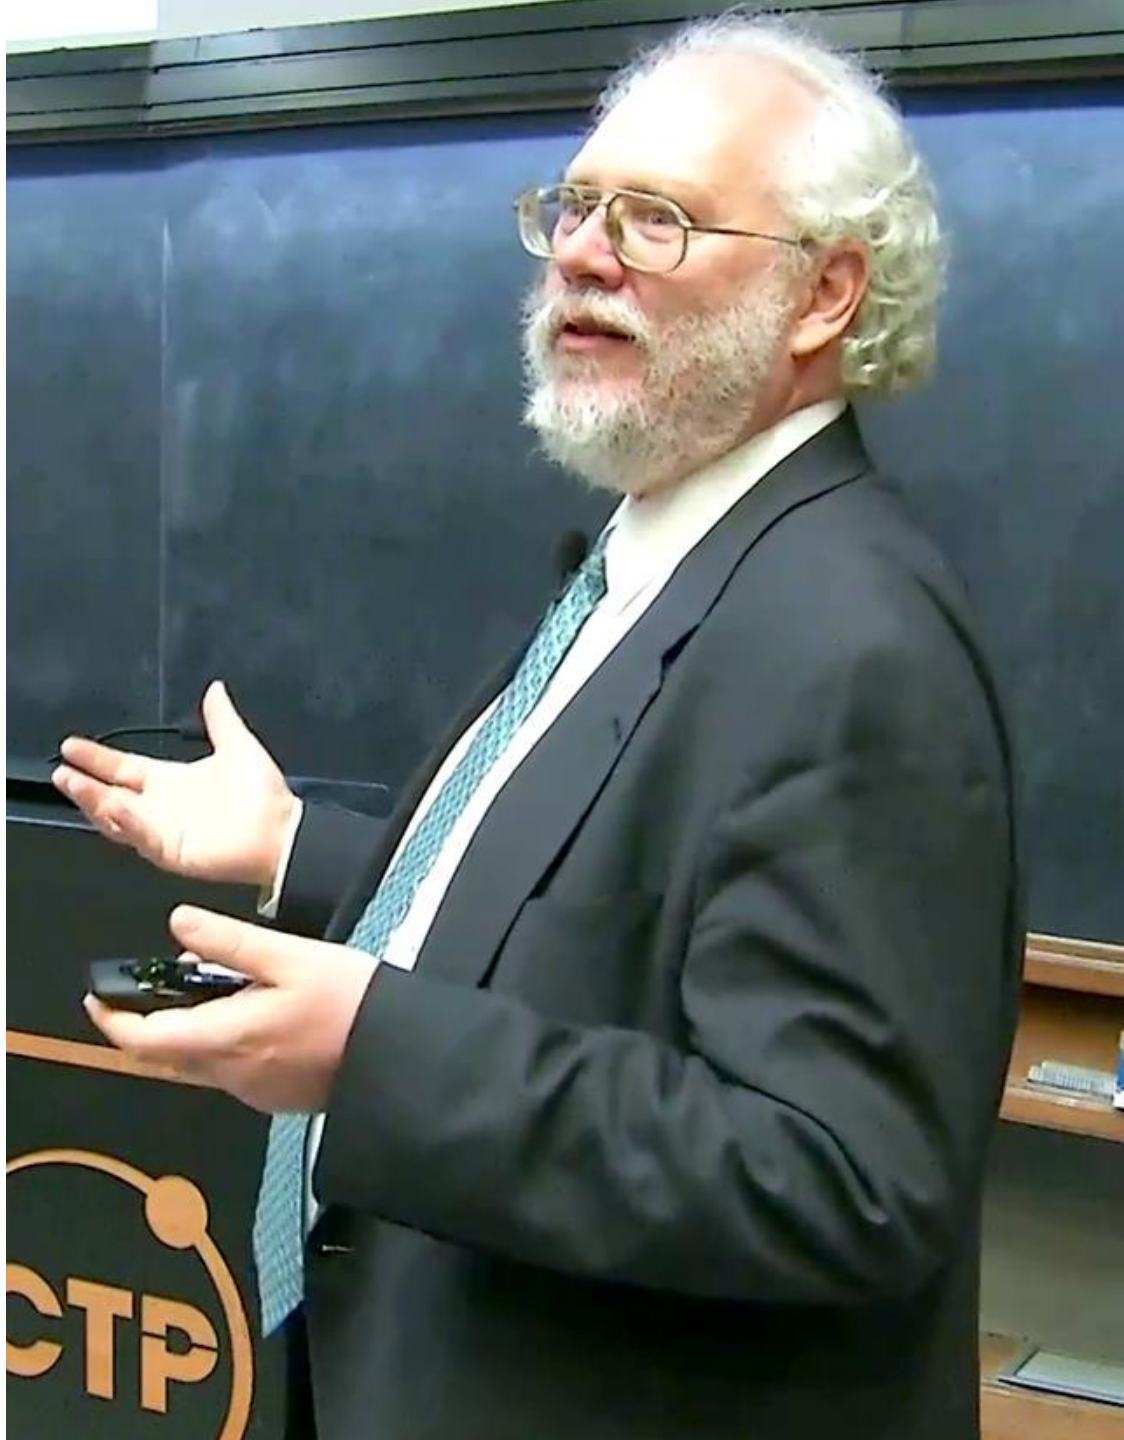

Peter W. Shor†

Abstract

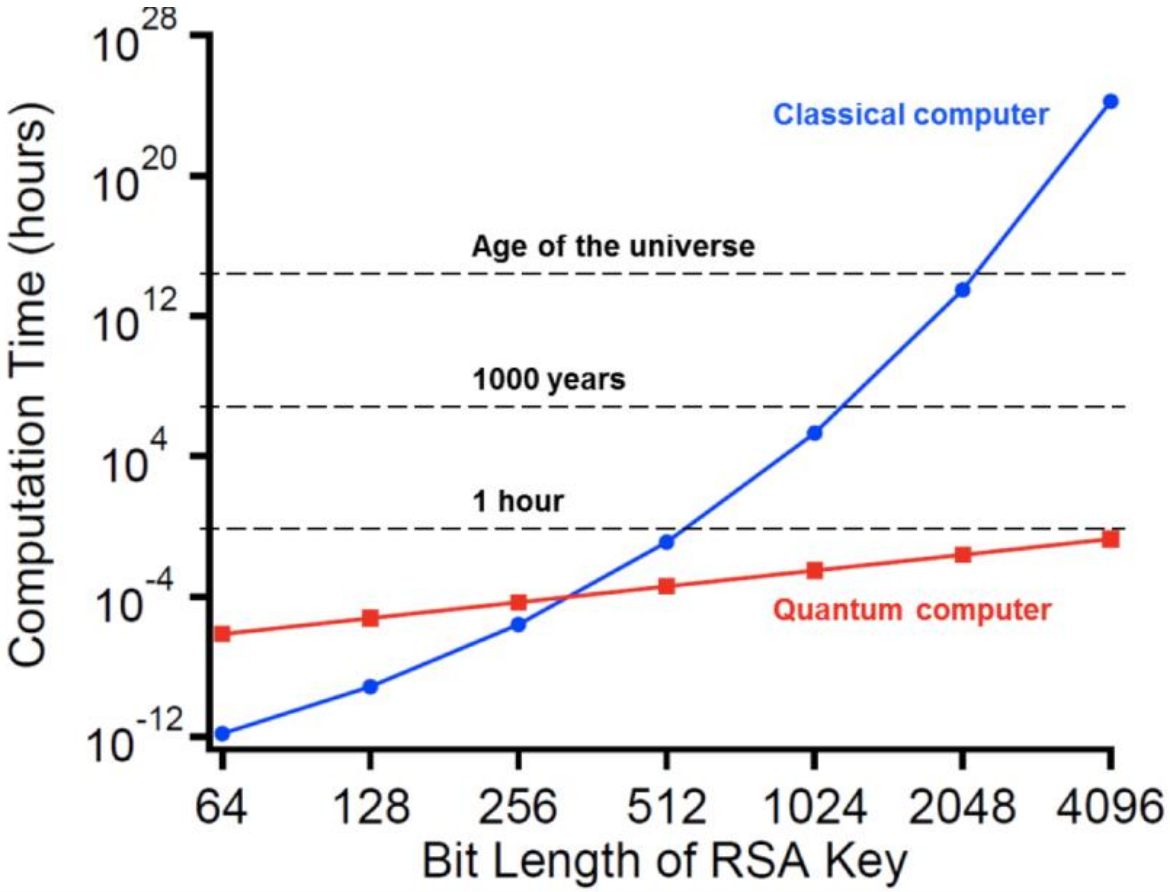

A digital computer is generally believed to be an efficient universal computing device; that is, it is believed able to simulate any physical computing device with an increase in computation time by at most a polynomial factor. This may not be true when quantum mechanics is taken into consideration. This paper considers factoring integers and finding discrete logarithms, two problems which are generally thought to be hard on a classical computer and which have been used as the basis of several proposed cryptosystems. Efficient randomized algorithms are given for these two problems on a hypothetical quantum computer. These algorithms take a number of steps polynomial in the input size, e.g., the number of digits of the integer to be factored.

State of the post-quantum Internet in 2025

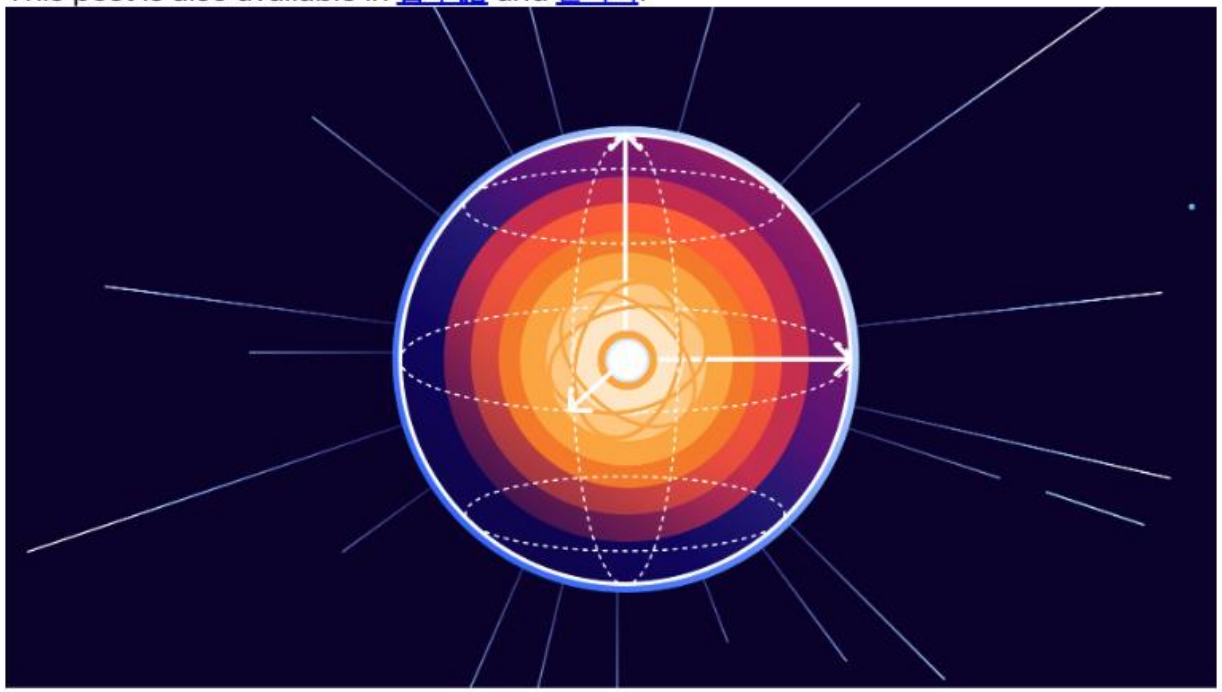

2025-10-28

Bas Westerbaan

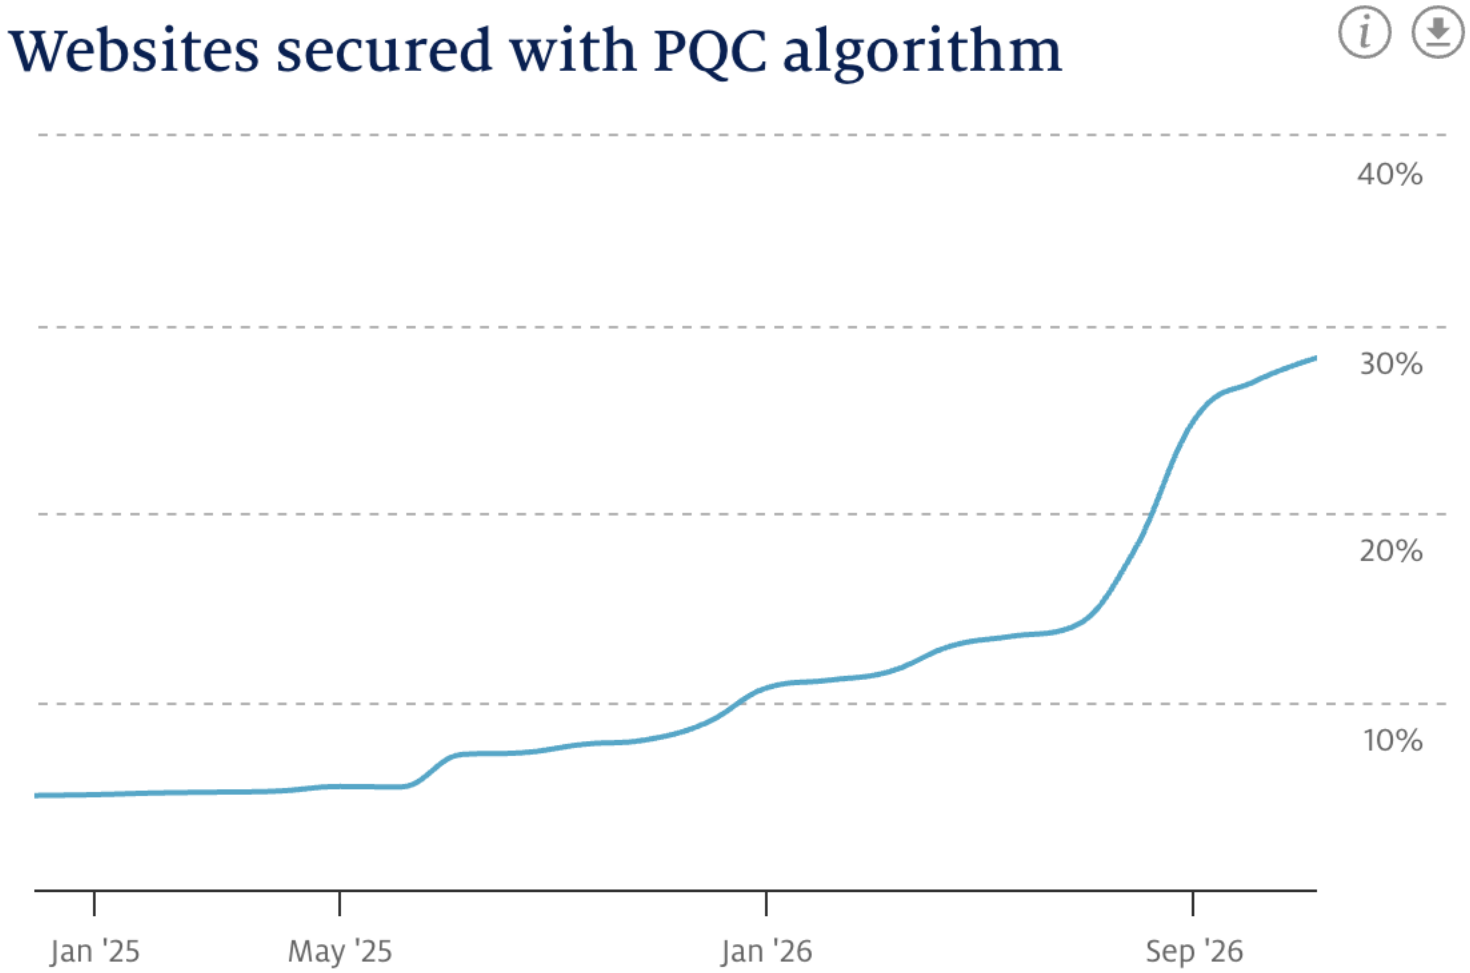

41 min read

This post is also available in 日本語 and 한국어.

This week, the last week of October 2025, we reached a major milestone for Internet security: the majority of human-initiated traffic with Cloudflare is using post-quantum encryption mitigating the threat of harvest-now/decrypt-later.
